The innovation of the final moult and the origin of insect metamorphosis

Institute of Evolutionary Biology (CSIC-Universitat Pompeu Fabra), Passeig Marítim 37, 08003 Barcelona, Spain

The three modes of insect postembryonic development are ametaboly, hemimetaboly and holometaboly, the latter being considered the only significant metamorphosis mode. However, the emergence of hemimetaboly, with the genuine innovation of the final moult, represents the origin of insect metamorphosis and a necessary step in the evolution of holometaboly. Hemimetaboly derives from ametaboly and might have appeared as a consequence of wing emergence in Pterygota, in the early Devonian. In extant insects, the final moult is mainly achieved through the degeneration of the prothoracic gland (PG), after the formation of the winged and reproductively competent adult stage. Metamorphosis, including the formation of the mature wings and the degeneration of the PG, is regulated by the MEKRE93 pathway, through which juvenile hormone precludes the adult morphogenesis by repressing the expression of transcription factor E93, which triggers this change. The MEKRE93 pathway appears conserved in extant metamorphosing insects, which suggest that this pathway was operative in the Pterygota last common ancestor. We propose that the final moult, and the consequent hemimetabolan metamorphosis, is a monophyletic innovation and that the role of E93 as a promoter of wing formation and the degeneration of the PG was mechanistically crucial for their emergence.

1. Introduction

The main modes of postembryonic development in insects are ametaboly, hemimetaboly and holometaboly. Ametabolan insects do not undergo significant morphological transformations during their life cycle, and they continue to moult after becoming reproductively competent. This is seen in the Archaeognatha and Zygentoma. Hemimetabolan species hatch as nymphs that are morphologically similar to the adults and grow progressively until the last nymphal instar, which mouls into the adult stage. The adults differ from the nymphs mainly by having wings and genitalia, and because they no longer moult. Hemimetaboly is characteristic of the Palaeoptera, Polynoeoptera and Paraneoptera. Holometabolan insects hatch as larvae that are morphologically very divergent from the adults; they progressively grow through successive moults until the last larval instar and the pupa, often quiescent and similar to the adult, and then to the adult stage, with flying wings and functional genitalia, which no longer moults. All the Endopterygota are holometabolous [1–5].

Evolutionarily, ametaboly is the most ‘ancestral’ mode of postembryonic development. Ametaboly gave rise to hemimetaboly, which in turn gave rise to holometaboly [3–5]. Often, holometaboly is considered the only significant type of metamorphosis [6–8], and some authors even consider metamorphosis and holometaboly to be synonymous [9]. For this reason, studies have focused predominantly on the evolution of holometaboly [1,2]. However, the emergence of hemimetaboly, consubstantial with the innovation of the final moult, represents the origin of insect metamorphosis and a necessary step in the evolution of holometaboly, the process through which more than 80% of extant insects metamorphose [10], even if this was not the case during the
Palaeozoic. In this context, the present essay contends that the emergence of hemimetaboly should be considered one of the great innovations in insect evolution.

Hemimetaboly emerged with the clade Pterygota (viz. presence of wings), as we have no fossil record of any apterous hemimetabolan insects in the Devonian [11,12]. The innovation of hemimetabolan metamorphosis after the emergence of wings [13–15] is probably not coincidental, but rather hemimetaboly could have come about as a consequence of wing acquisition. Hemimetabolan species, like the firebrat Thermobia domestica (Zygentoma), undergo morphological modifications throughout their life cycle, including the apparition of scales between the third and the fourth nymphal instars [16]. Therefore, the most genuine innovation after the emergence of wings is the final moult, mainly achieved through the degeneration of the prothoracic gland (PG), which produces the moulting hormone, and perhaps also through the adult commitment of epidermal cells, which become incapable of producing a new cuticle. This would happen after the full formation of the flying and reproductively competent adult stage. This work aims to explore the circumstances that surrounded and facilitated the transition from ametaboly to hemimetaboly, and the presumptive mechanisms that made this transition possible.

2. The phylogenetic and Palaeontological framework

Phylogenetic and palaeontological data indicate that wings and hemimetaboly originated during the early–middle Devonian, some 400 Ma [11,12] (figure 1). The fact that extant pterygotes are monophyletic [11,12], and that the wing types of all insect orders are constructed in the same way, both in extant and fossil species [17], strongly suggest that wings evolved only once. The monophyly of Pterygota, in turn, suggests that there was a single origin of hemimetaboly and that this could be linked to the emergence of wings.

Fossils can provide direct evidence of the origin and morphological evolution of metamorphosis. Nevertheless, studies documenting the fossils of successive stages of the same species are scarce [18]. The most complete series of Palaeozoic fossils of successive nymphal phases are of Megasecoptera and Ephemeroptera, as reported, for example, by Kukalová-Peck [13–15]. These series show how the wings of the early nymphs were small and curved backwards. With successive molts, the wings increased in length, became less curved and tended to adopt a position perpendicular to the body. In the adult, the wings were slender, with the basal region narrower than the distal, and practically perpendicular to the body axis [13–15,18] (figure 2a). Another type of wing development is exemplified by Palaeozoic roachoid nymphs, early representatives of the Blattodea lineage, which broadly resemble extant cockroach nymphs (figure 2b). In extant cockroaches, the wing pads develop posteriorly and the attachment area was restricted to the lateral tegrum [18].

In those fossil groups with external nymphal winglets, such as the Ephemeroptera and Megasecoptera, selective pressures might have acted to facilitate the concealment of
these in juveniles (figure 2c) [13]. It is possible that, among other advantages, concealed winglets facilitated moulting by reducing mechanical problems during ecdisis and the shedding off the exuvia. The evolution of Palaeozoic roachoids could have followed the same tendency, with the winglets concealed by being retracted backwards and attached to the body. Although it is difficult to discern in fossil samples, the winglet morphology of Palaeozoic roaches suggests they were not membranous. They are more reminiscent of the pterotheca or cuticular pocket that envelops the wing primordia of extant cockroaches [19].

### 3. The final moult as a crucial innovation in the origin of the Pterygota

Fossils of Palaeozoic nymphs suggest that ‘ancestral’ Pterygota had a remarkable diversity of morphologies and life cycles. This led Kukalová-Peck [13,14] to argue that, in the Carboniferous, the insect life cycle comprised a high number of moults, and that older nymphs had articulated, functional wings. Kukalová-Peck [14] suggested that a number of late nymphal stages could have become ‘condensed’ into the adult stage, and that also younger nymphs would have undergone various degrees of ‘condensation’. The general tendency would have been to reduce the number of moults, and differences in the juvenile/imaginal specialization in the various stages would have produced the life cycle diversity observed in the fossils.

The sometimes disparate nymphal morphologies (as between mayflies and roachoids, for example), and the different life cycles revealed by the Palaeozoic fossils suggested to Kukalová-Peck [13,14] that metamorphosis evolved independently and at distinct rates in the diverging hemimetabolan lineages. However, although hemimetabolan life cycles can be very different in terms of number of moults and nymphal morphologies, in all of them the development ends with a final moult. It is proposed here that this final moult was a crucial innovation in the evolution of insects, consubstantial with the origin of hemimetabolan metamorphosis. We also contend that there was a single origin of the final moult, in the origin of the monophyletic Pterygota. This hypothesis is supported by data on the mechanisms determining the degeneration of the PG and the final moult, as explained below.

The hypothesis of the monophyletic origin of the final moult is compatible with the diverse life cycles observed in the different hemimetabolan groups, which would have evolved independently in each lineage. It is also compatible with scenarios of life cycle evolution through the ‘condensation’ of late nymphal stages with articulated wings, as proposed by Kukalová-Peck [14]. The final moult could have been fixed immediately after the formation of the mature wings, membranous, without active epidermal cells and fully efficient for flying, although there may have been intermediate subimaginal stages with (precariously) flying wings, like in extant Ephemeroptera.
4. The case of Ephemeroptera

The Ephemeroptera are unique among extant insects in that they moult once more after forming flying wings. Thus, the last moult of the nymphal period does not achieve the definitive adult form, but rather a winged stage, known as a subimago, which morphologically resembles the adult. The outer and hind edges of wings in the subimago present a row of cilia, and their surface is covered with microtrichia, whereas the adult wings of most species lack these hairy structures [20]. The regulation of the subimago to imago moult is intriguing, because in some cases, the subimago stage lasts for minutes or a few hours before the ecdisis to the imago. Ecdysone measurements might help to explain how two so closely following moults can be regulated.

The evolutionary and functional sense of the subimago has been widely discussed. It has been proposed that the hydrofuge properties of the hairy surface of the subimago have a particular function, as these could help to overcome the hazards of transitioning from an aquatic nymph to a winged aerial form at the water–air interface [21]. Maiorana [22] conjectured that the subimaginal stage would allow the necessary growth to form a full-sized and reproducitively competent adult. The palaeontological data (see above) suggest that the subimago is a ‘primitive’ feature, conserved in extant species as a kind of relic of preadult winged instars of ‘ancestral’ mayflies. Thus, according to the currently accepted phylogenies (figure 1), the subimago appears to be a pleiomorphic conserved in extant mayflies. Then, the subimago (or the imago) would have been convergently lost in other extant Pterygota.

A few examples where the moult from subimago to adult is incomplete or absent are worth mentioning. In females of at least two species of Leptophlebiidae, the apolysis of the subimago to the adult occurs but the ecdisis does not. Oligoneuriinae mayflies are also peculiar because when mouling to the adult stage they shed off the exuvia from the body but retain the subimaginal cuticle on the wings. Finally, females of a few specialized species of Palingeniinae seem to have lost the adult stage, and the subimago is the last one [20]. Significantly, this feature was first reported by Swammerdam in 1675, when he discovered that adult males of Palingenia longicauda moult twice but females do so only once [23]. These examples suggest that evolution may favour the merging of winged stages in the life cycle of mayflies, as Kukalová-Peck [14] proposed, and as must have happened in other insect lineages where there is a single winged stage.

5. E93 and the MEKRE93 pathway

In extant hemimetabolans, the PG degenerates with the imaginal moult (see, for example [24,25]). The cell death process is associated with the hormonal and molecular mechanisms that regulate the metamorphosis, in general, which are condensed in the MEKRE93 pathway [26]. The metamorphosis-triggering action of E93 occurs in both hemimetabolans and holometabolans species [27], but in hemimetabolans metamorphosis, the MEKRE93 pathway is simpler: juvenile hormone (JH) bound to its receptor Methoprene tolerant (Met) [28] induces the expression of Krüppel homolog 1 (Kr-h1), and Kr-h1 represses the expression of E93, thus precluding metamorphosis [26,29] (figure 3a). As exemplified in the German cockroach, Blattella germanica, JH production ceases early in the last nymphal stage, the expression of Kr-h1 decreases and that of E93 increases, bringing about the metamorphic moult (figure 3b). The study of mature wing formation in Drosophila melanogaster shows that E93 acts as a chromatin modifier, enabling or preventing expression in certain genetic regions [30]. This helps to explain the pleiotropic action of E93, which simultaneously triggers the development of the different tissues and organs that configure the adult morphology.

Additionally, E93 is a key factor regulating cell death processes, such as midgut and fat body remodelling, and
salivary gland degeneration at the onset of metamorphosis in *D. melanogaster* [31–34]. These antecedents suggest the hypothesis that E93 might also be involved in the degeneration of the PG in holometabolan and hemimetabolan species. In the hemimetabolan B. germanica, RNAi depletion of E93 in the last nymphal instar precludes metamorphosis, and the nymphs moult to successive supernumerary nymphs [26,27]. As expected, the PG does not degenerate in E93-depleted supernumerary nymphs (figure 4).

Among the hemimetabolan insects, the MEKRE93 pathway operates in Polyneoptera [26,27,35] and Paraneoptera [36,37]. In Palaeoptera, a transcriptomic study conducted on the Ephemeroptera *Cloeon viridulum* revealed that the expression of Kr-h1 decreases progressively from young to mature nymphs, and to the subimago [38], suggesting that Kr-h1 represses metamorphosis. Unfortunately, expression of E93 was not reported. In the neotenic Hemiptera Cocco- morpha (Paraneoptera), male postembryonic development includes the quiescent stages of ‘prepupa’ and ‘pupa’ that precede the adult. Interestingly, the expression of Kr-h1 decreases in the ‘prepupa’ phase, while the expression of E93 increases [39,40]. This suggests that in these hemimetabolan species with complex life cycles, the MEKRE93 pathway may operate similarly to the way it does in other hemimetabolan species.

6. The origin of metamorphosis from a mechanistic perspective

Possibly, the ancestral role of the JH in insects was related to reproductive functions, a role that is still played in Zygen- toma [41,42] (see below) and in most metamorphosing insects [43], and even in crustaceans [44], the sister group of the hexapods [45]. Subsequently, JH would have been further co-opted to perform functions related to development, in particular, to prevent metamorphosis. In this context, data reported above suggest that the MEKRE93 pathway regulates metamorphosis in the extant hemimetabolan clades Palaeo- tera, Polyneoptera and Paraneoptera and that it would have operated in the last common ancestor of the hemimetabolan groups. If so, then a single mechanism, the MEKRE93 pathway and E93 in particular, might have simultaneously regulated wing formation and PG degeneration, and hence the final moult (i.e. hemimetabolan metamorphosis), at the origin of the Pterygota.

Much progress has been made in explaining the evolutionary origin of insect wings. The theory that currently enjoys the greatest consensus postulates a dual origin, tergal and pleural, of the wings (see [46] for a review). However, there are no theories as to which factors and mechanisms might have triggered and regulated the formation and maturation of the ‘ancestral’ wing. What we currently know about E93 makes it a prime candidate to be one of the key factors. From a mechanistic point of view, one of the first innovations in the ‘ancestor’ of the Pterygota could have been the upregulation of E93 expression in mature nymphs, mediated by the ecdysone signalling. An increase in the expression of E93 could have contributed to the maturation of the wings, and, in turn, to the degeneration of the PG. E93 could also contribute to the adult commitment of epidermal cells, thus making them incompetent to produce a new cuticle, even in the presence of the circulating ecdysteroids produced by the adult ovary (reviewed in [47]). In extant insects, the pleiotropic action of E93 appears to be facilitated by its properties as a chromatin modifier, enabling or preventing expression in certain genomic regions [30]. If these properties are ‘ancestral’, then they could have been a versatile way to turn the appropriate genes on (or off) to regulate new processes, including wing maturation and PG degeneration. Another necessary requirement would be for JH to play an inhibitory role in metamorphosis, possibly through Kr-h1 repressing E93, as in extant insects. This would have allowed proper growth of the nymph. Refinements of this incipient MEKRE93 pathway, driven by natural selection, would have adjusted the regulation of the genes involved, mainly Kr-h1 and E93, in different tissues and at the appropriate times, producing in a more precise system of regulation. Differential solutions for ‘condensing’ juvenile and/or subadult stages in different lineages [14] would have generated the life cycle diversity that we observe today among the hemimetabolan insects. The same Kr-h1–E93 axis

Figure 4. Depletion of E93 in the last nymphal instar of the cockroach *Blattella germanica* inhibits metamorphosis. The last nymphal instar (sixth) moult into a supernumerary (seventh) nymphal instar, with full nymphal features, including the absence of wings, instead moulting to a winged adult (left). After the imaginal moult, from the sixth nymphal instar, the prothoracic gland (PG) degenerates within the first days of adult life, but the E93-depleted, supernumerary (seventh) nymphal instar keeps an active PG and can moult again (right). Photos from Carolina G. Santos (left) and Orathai Kamsoi (right).
could have regulated the tendency to attenuate the development of the wing pads in the juvenile phases [13] (figure 5).

7. The components of the MEKRE93 pathway predate the origin of Pterygota

The Met and Kr-h1 genes are present in T. domestica [48], a representative of the Zygentoma, the sister group of pterygote insects and which has ametabolan development. JH is involved in vitellogenesis in T. domestica [41,42], therefore, Met, and perhaps Kr-h1, might operate in this reproductive function. Indeed, there is functional evidence that T. domestica Met actually binds JH III [28]. Moreover, the degree of amino acid sequence conservation of the two corresponding proteins, Met and Kr-h1, in T. domestica, as compared with the corresponding orthologues in pterygote insects, is very high [48], suggesting conservation of general functions. Intriguingly, we have found that T. domestica also has the E93 gene (electronic supplementary material, figure S1), the last component of the MEKRE93 pathway. Thermobia domestica E93 contains the typical two helix-turn-helix DNA binding motifs of the pipsqueak family (RHF-1 and RHF-2), and, in general, the sequence is highly conserved with respect to other pterygote orthologues. Indeed, the phylogenetic analysis of representative insect E93 orthologues, including T. domestica, as well as the Diplura Catajapyx aquilonaris as an hexapod external group, reveals a topology which perfectly matches that recovered in the most recent and robust phylogenetic studies in insects [11,12] (figure 6). The conservation of T. domestica E93 is greatest in the RHF-1 and RHF-2 motifs, which are, respectively, 97% and 93% identical to those of B. germanica E93, and 89% and 98% to those of Nilaparvata lugens (electronic supplementary material, figure S2). In the hemimetabolans species B. germanica and N. lugens, it has been experimentally demonstrated that E93 acts as a metamorphosis trigger [26,27,37].

The Zygentoma do not metamorphose, but they do undergo changes throughout their life cycle, the most apparent of which is the formation of scales in early instars. T. domestica, scales appear towards the middle of the third nymphal instar [16], and integument transplantation experiments, as well as corpora allata (CA; the JH producing glands) volume and activity measurements [51], suggest that these scales appear shortly after a transient decrease in JH. According to Watson [51], when a fragment of integument from a first nymphal instar of T. domestica was implanted in an adult that was going to moult, scales formed in the implanted fragment, suggesting that scale formation is determined by a humoral factor. CA measurements showed that the minimal gland volume is found in the early–mid third nymphal instar, in other words prior to scale formation. It is worth noting that CA volume correlates approximately with CA activity, as demonstrated by techniques for measuring JH production [52]. Finally, the JH activity of the CA, when tested using the Gilbert and Schneiderman bioassay [53], was shown to be minimal in the third stage [51]. The data as a whole suggest that the formation of scales in early nymphs of T. domestica is repressed by JH.

8. Testable hypotheses

A point to be tested is whether the MEKRE93 pathway operates in Palaepoptera, to confirm that it is conserved in the three extant insect superorders. Ephemeroptera may be the choice case study, as it allows us to look at not only the regulation of metamorphosis in general but also that of the exceptional subimaginal expression patterns and functional genomics experiments would show whether Kr-h1 transduces the antimetamorphic signal of JH, and whether E93 promotes...
metamorphosis and is repressed by Kr-h1. It should also provide an insight into how PG degeneration is prevented in the subimago.

The life cycle of Thysanoptera and Hemiptera Coccomorpha, which are paraneopteran and hemimetabolan groups, includes one or more preadult, pupa-like quiescent stages. Understanding how these stages are determined could reveal whether there are similar mechanisms that regulate the holometabolan pupa. If so, this would suggest that the quiescent states of these Paraneopera represent an exaptation in the evolution of holometabolan metamorphosis and the pupal stage. In Thysanoptera and male Coccomorpha, the expression of Kr-h1 decreases progressively from nymphs to the preadult stages and ceases in the adult [39,54]. This suggests that Kr-h1 represses metamorphosis in these insects. In male Coccomorpha, moreover, E93 expression increases in the preadult stages, at the same time that of Kr-h1 decreases [40]; this suggests that Kr-h1 represses E93, whereas E93 triggers metamorphosis [26]. Although there are clear technical difficulties owing to the minute size of these insects, it would be interesting to undertake functional studies where Kr-h1 and E93 were depleted and suppressed, in order to

---

**Figure 6.** Phylogenetic analysis of E93 orthologues of Palaeoptera, Polyneoptera, Paraneoptera and Endopterygota species, as well as Thermobia domestica, as a representative of the ametabolan Zygentoma, and Catajapex aquilonaris (Hexapoda, Diplura) as an hexapodan external group. Alignments were carried out with ClustalX [49] and phylogenetic reconstruction with RAxML [50], based on the maximum-likelihood principle, a JTT matrix, a gamma model of heterogeneity rate, and using empirical base frequencies and estimating proportions. The data were bootstrapped for 100 replicates. Bootstrap values are indicated in the subclass, super-order and order nodes. Scale bar indicates the number of substitutions per site. Complete species names and accession data of the respective sequences are detailed in the electronic supplementary material, table S1.
confirm that the MEKRE93 pathway operates in these groups. Functional studies would also shed light on how Kr-h1 and E93, and perhaps Broad complex, a factor that determines the pupal stage in holometabolous species [55], interact with each other to determine these pupa-like stages.

The main hypotheses of this work are that the first moult, and the consequent hemimetabolous metamorphosis, is a monophyletic innovation and that the role of E93 as a promotor of wing formation and the degeneration of the PG was mechanistically crucial for this innovation. Demonstrating that E93 is fundamental in wing formation and PG degeneration is therefore essential. The role of E93 in the formation of mature wings is part of the morphogenetic action of this factor in metamorphosis [26,27], and the role of E93 on wing formation has been specifically described in D. melanogaster [30]. Data available on PG degeneration in cockroaches show that supernumerary nymphs obtained in E93-depleted insects have active PG (figure 4), and moult again. The survival of PG in these nymphs must be considered in the context of metamorphosis inhibition, in general. It would be interesting to uncouple the effect of E93 on adult morphogenesis from its possible direct role in PG degeneration. This could be undertaken in D. melanogaster by suppressing the expression of E93 specifically in the PG cells. In hemimetabolous species, the possible specific role of E93 in PG degeneration could be studied using systemic RNAi, but depleting the expression of E93 towards the end of the last nymphal stage, when its morphogenetic effects have already been implemented. The same approach could be followed to study whether E93 is involved in the adult commitment of the epidermal cells.

The study of the role of Kr-h1 and E93 in Zygentoma has an obvious evolutionary interest. The formation of scales in young nymphs of T. domestica might be determined by a transient decrease of JH [51]. Treatment of pre-scaled juveniles with JH would allow us to assess whether the formation of scales is prevented by this hormone. Moreover, expression studies could suggest whether Kr-h1 is involved in the transcription of the JH signal, and whether E93 is involved in scale formation. The depletion or suppression of Kr-h1 and E93 expression could show whether these factors play any role in regulating scale formation, or any other morphological transformation, such as the formation of functional genitalia. Heritable targeted mutagenesis based on CRISPR/Cas9 approaches has been recently developed in T. domestica [56], which makes possible the above functional studies. If morphogenetic functions of E93 are demonstrated in the Zygentoma, this would represent an exaptation for the roles of E93 in the formation of the adult in hemimetabolous metamorphosis. The degeneration of the PG (thus determining the last moult), and the possible role of E93 in this process, would therefore be the most genuine innovation in the transition from ametaboly to hemimetaboly.
